Grouping and summarizing

The GRAPH Courses team

November 2022

This document serves as an accompaniment for a lesson found on https://thegraphcourses.org.

The GRAPH Courses is a project of the Global Research and Analyses for Public Health (GRAPH) Network, with the support of the World Health Organization (WHO) and other partners

Introduction
Learning objectives
The Yaounde COVID-19 dataset
What are summary statistics?
<pre>Introducing dplyr::summarize()</pre>
Grouped summaries with dplyr::group by()
Grouping by multiple variables (nested grouping)
Ungrouping with dplyr::ungroup() (why and how)
Counting rows
Counting rows that meet a condition
dplyr::count()
Including missing combinations in summaries
Wrap-up

Introduction

You currently know how to keep your data entries of interest, how keep relevant variables and how to modify them or create new ones.

Now, we will take your data wrangling skills one step further by understanding how to easily extract summary statistics, through the verb summarize(), such as calculating the mean of a variable.

Moreover, we will begin exploring a crucial verb, $group_by()$, capable of grouping your variables together to perform grouped operations on your data set.

Let's go!

Learning objectives

- 1. You can use dplyr::summarize() to extract summary statistics from datasets.
- 2. You can use <code>dplyr::group_by()</code> to group data by one or more variables before performing operations on them.
- 3. You understand why and how to ungroup grouped data frames.
- 4. You can use dplyr::n() together with group_by()-summarize() to count rows per group.
- 5. You can use sum() together with group_by()-summarize() to count rows that meet a condition.
- 6. You can use dplyr::count() as a handy function to count rows per group.

The Yaounde COVID-19 dataset

In this lesson, we will again use data from the COVID-19 serological survey conducted in Yaounde. Cameroon.

```
yaounde <- read_csv(here::here('data/yaounde_data.csv'))

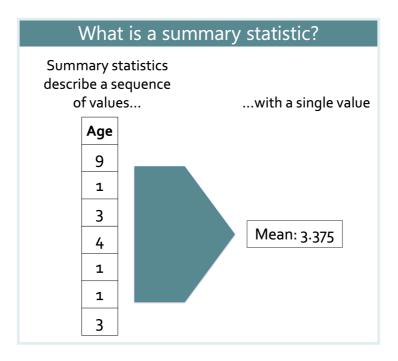

# A smaller subset of variables
yao <- yaounde %>% select(
   age, age_category_3, sex, weight_kg, height_cm,
   neighborhood, is_smoker, is_pregnant, occupation,
   treatment_combinations, symptoms, n_days_miss_work, n_bedridden_days,
   highest_education, igg_result)
```

```
## # A tibble: 971 × 15
##
    age age_category_3 sex weight_kg height_cm
## <dbl> <chr> <chr> <dbl> <dbl>
## 1 45 Adult
                     Female
                                95
## 2
      55 Adult
                     Male
                                 96
                                         185
## 3
      23 Adult
                                  74
                     Male
                                          180
                     Female
## 4 20 Adult
                                 70
                                          164
                                 67
## 5 55 Adult
                     Female
                                          147
## 6 17 Child
                     Female
                                 65
                                          162
## 7
      13 Child
                     Female
                                 65
                                          150
## 8 28 Adult
## 9 30 Adult
                     Male
                                  62
                                          173
                     Male
                                  7.3
                                          170
## 10
      13 Child
                      Female
                                  56
                                          153
## # ... with 961 more rows, and 10 more variables:
## # neighborhood <chr>, is smoker <chr>, ...
```

See the first lesson in this chapter for more information about this dataset.

What are summary statistics?

A summary statistic is a single value (such as a mean or median) that describes a sequence of values (typically a column in your dataset).

Summary statistics can describe the center, spread or range of a variable, or the counts and positions of values within that variable. Some common summary statistics are shown in the diagram below:

Examples of summary statistics

Summary statistic	R code	Output
Counts		
No. of elements	<pre>dplyr::n(age)</pre>	6
No. of distinct elements	<pre>dplyr::n_distinct(age)</pre>	4
Position		
First element	<pre>dplyr::first(age)</pre>	9
Last element	<pre>dplyr::last(age)</pre>	2
3rd element	<pre>dplyr::nth(age, 3)</pre>	4
Center		
Mean	mean(age)	3.3
Median	median(age)	2
Spread		
Standard deviation	sd(age)	2.9
Interquartile range	IQR(age)	1.5
Range		
Minimum	min(age)	1
Maximum	<pre>max(age)</pre>	9
25th quantile	quantile(age, 0.25)	2

Computing summary statistics is a very common operation in most data analysis workflows, so it will be important to become fluent in extracting them from your datasets. And for this task, there is no better tool than the {dplyr} function summarize()! So let's see how to use this powerful function.

Introducing dplyr::summarize()

To get started, it is best to first consider how to get simple summary statistics *without* using summarize(), then we will consider why you *should* actually use summarize().

Imagine you were asked to find the mean age of respondents in the yao data frame. How might you do this in base R?

First, recall that the dollar sign function, \$, allows you to extract a data frame column to a vector:

```
yao$age # extract the `age` column from `yao`
```

To obtain the mean, you simply pass this yao\$age vector into the mean () function:

```
mean(yao$age)
```

```
## [1] 29.01751
```

And that's it! You now have a simple summary statistic. Extremely easy, right?

So why do we need <code>summarize()</code> to get summary statistics if the process is already so simple without it?We'll come back to the <code>why</code> question soon. First let's see <code>how</code> to obtain summary statistics with <code>summarize()</code>.

Going back to the previous example, the correct syntax to get the mean age with summarize() would be:

```
yao %>%
   summarize(mean_age = mean(age))

## # A tibble: 1 × 1
## mean_age
## <dbl>
## 1 29.0
```

The anatomy of this syntax is shown below. You simply need to input name of the new column (e.g. mean_age), the summary function (e.g. mean()), and the column to summarize (e.g. age).

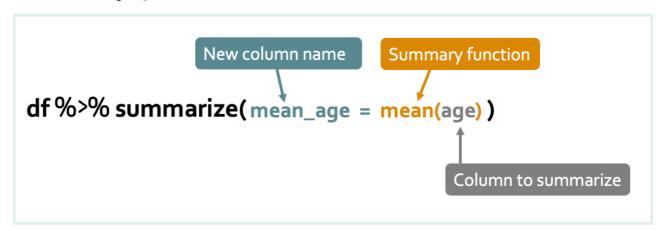

Fig. Basic syntax for the summarize () function.

You can also compute multiple summary statistics in a single summarize () statement. For example, if you wanted both the mean and the median age, you could run:

```
## # A tibble: 1 × 2
## mean_age median_age
## <dbl> <dbl>
## 1 29.0 26
```

Nicel

Now, you should be wondering why summarize() puts the summary statistics into a data frame, with each statistic in a different column.

The main benefit of this data frame structure is to make it easy to produce *grouped* summaries (and creating such grouped summaries will be the primary benefit of using summarize()).

We will look at these grouped summaries in the next section. For now, attempt the practice questions below.

Use summarize() and the relevant summary functions to obtain the mean, median and standard deviation of respondent weights from the weight kg variable of the yao data frame.

Your output should be a data frame with three columns named as shown below:

mean_weight_kg median_weight_kg sd_weight_kg

Use summarize() and the relevant summary functions to obtain the minimum and maximum respondent heights from the $height_cm$ variable of the yao data frame.

Your output should be a data frame with two columns named as shown below:

min_height_cm max_height_cm

```
Q_height_summary <-
   yao %>%
```

```
PRACTICE

(in RMD)
```

```
.CHECK_Q_height_summary()
.HINT_Q_height_summary()
```

Grouped summaries with dplyr::group by()

As its name suggests, dplyr::group_by() lets you group a data frame by the values in a variable (e.g. male vs female sex). You can then perform operations that are split according to these groups.

What effect does <code>group_by()</code> have on a data frame? Let's try to group the <code>yao</code> data frame by sex and observe the effect:

```
yao %>%
group_by(sex)
```

```
## # A tibble: 971 × 15
## # Groups: sex [2]
      age age category 3 sex weight kg height cm
##
    ##
## 1
      45 Adult
                    Female
                               95
                                      169
## 2
      55 Adult
                   Male
                               96
                                       185
                   Male
  3
      23 Adult
                               74
##
                                       180
     20 Adult
                   Female
##
  4
                               70
                                       164
## 5
     55 Adult
                   Female
                              67
                                       147
## 6
     17 Child
                   Female
                               65
## 7 13 Child
                   Female
                               65
                                       150
## 8 28 Adult
                   Male
                               62
                                       173
## 9
     30 Adult
                   Male
                               7.3
                                       170
     13 Child
## 10
                    Female
                              56
                                      153
## # ... with 961 more rows, and 10 more variables:
     neighborhood <chr>, is smoker <chr>, ...
```

Hmm. Apparently nothing happened. The one thing you *might* notice is a new section in the header that tells you the grouped-by variable—sex—and the number of groups—2:

```
# A tibble: 971 × 10
# Groups: sex [2]
```

Apart from this header however, the data frame appears unchanged.

But watch what happens when we chain the group_by() with the summarize() call we used in the previous section:

```
yao %>%
  group_by(sex) %>%
  summarize(mean_age = mean(age))
```

You get a different summary statistic for each group! The statistics for women are in one row and those for men are in another. (From this output data frame, you can tell that, for example, the mean age for female respondents is 29.5, while that for male respondents is 28.4)

As was mentioned earlier, this kind of grouped summary is the primary reason the summarize() function is so useful!

Let's see another example of a simple group by () + summarize () operation.

Suppose you were asked to obtain the maximum and minimum weights for individuals in different neighborhoods in the yao data frame. First you would group_by() the neighbourhood variable, then call the max() and min() functions inside summarize():

```
## # A tibble: 9 \times 3
  neighborhood max weight min weight
## <chr> <dbl> <dbl>
                    128
## 1 Briqueterie
                              20
## 2 Carriere
                    129
                               14
## 3 Cité Verte
                    118
                               16
                     135
## 4 Ekoudou
                                15
                     96
                               19
## 5 Messa
## 6 Mokolo
                    162
                               16
## 7 Nkomkana
                    161
                               15
                    105
                               15
## 8 Tsinga
## 9 Tsinga Oliga
                    100
                                17
```

Great! With just a few code lines you are able to extract guite a lot of information.

Let's see one more example for good measure. The variable $n_{days_miss_work}$ tells us the number of days that respondents missed work due to COVID-like symptoms. Individuals who reported no COVID-like symptoms have an NA for this variable:

```
yao %>%
select(n_days_miss_work)
```

```
## # A tibble: 971 × 1
## n days miss work
##
              <dbl>
## 1
                  0
## 2
                  NA
## 3
                  NA
##
   4
                   7
## 5
                  NA
## 6
                  7
## 7
                  0
## 8
                  0
## 9
                  0
## 10
## # ... with 961 more rows
```

To count the total number of work days missed for each sex group, you could try to run the sum() function on the n days miss work variable:

```
yao %>%
group_by(sex) %>%
summarise(total_days_missed = sum(n_days_miss_work))
```

Hmmm. This gives you NA results because some rows in the $n_{days_miss_work}$ column have NAs in them, and R cannot find the sum of values containing an NA. To solve this, the argument na.rm = TRUE is needed:

```
yao %>%
  group_by(sex) %>%
  summarise(total_days_missed = sum(n_days_miss_work, na.rm = TRUE))
```

The output tells us that across all women in the sample, 256 work days were missed due to COVID-like symptoms, and across all men, 272 days.

So hopefully now you see why summarize() is so powerful. In combination with group_by(), it lets you obtain highly informative grouped summaries of your datasets with very few lines of code.

Producing such summaries is a very important part of most data analysis workflows, so this skill is likely to come in handy soon!

summarize() produces "Pivot Tables"

Use group_by() and summarize() to obtain the mean weight (kg) by smoking status in the yao data frame. Name the average weight column weight_mean

The output data frame should look like this:

is_smoker	weight_mean
Ex-smoker	
Non-smoker	
Smoker	
NA	

Use <code>group_by()</code>, <code>summarize()</code>, and the relevant summary functions to obtain the minimum and maximum heights for each sex in the <code>yao</code> data frame.

Your output should be a data frame with three columns named as shown below:

sex	min_height_cm	max_height_cm
Female		
Male		

Use $group_by()$, summarize(), and the sum() function to calculate the total number of bedridden days (from the $n_bedridden_days$ variable) reported by respondents of each sex.

Your output should be a data frame with two columns named as shown below:

neighborhood total_bedridden_days

Female

Male

Grouping by multiple variables (nested grouping)

It is possible to group a data frame by more than one variable. This is sometimes called "nested" grouping.

Let's see an example. Suppose you want to know the mean age of men and women *in each neighbourhood* (rather than the mean age of *all* women), you could put both sex and neighborhood in the group by () statement:

```
yao %>%
  group_by(sex, neighborhood) %>%
  summarize(mean_age = mean(age))

## `summarise()` has grouped output by 'sex'. You can override using the
`.groups` argument.

## # A tibble: 18 × 3
## # Groups: sex [2]
```

```
## 1 Female Briqueterie
                         31.6
## 2 Female Carriere
                          28.2
                         31.8
## 3 Female Cité Verte
                         29.3
## 4 Female Ekoudou
## 5 Female Messa
                         30.2
## 6 Female Mokolo
                         28.0
   7 Female Nkomkana
                         33.0
##
                         30.6
## 8 Female Tsinga
## 9 Female Tsinga Oliga
                         24.3
## 10 Male Briqueterie
                         33.7
## 11 Male Carriere
                         30.0
## 12 Male Cité Verte
                         27.0
                         25.2
## 13 Male Ekoudou
## 14 Male Messa
                         23.9
## 15 Male Mokolo
                         30.5
## 16 Male Nkomkana
                         29.8
## 17 Male Tsinga
                         28.8
## 18 Male Tsinga Oliga
                         24.3
```

From this output data frame you can tell that, for example, women from Briqueterie have a mean age of 31.6 years, while men from Briqueterie have a mean age of 33.7 years.

The order of the columns listed in <code>group_by()</code> is interchangeable. So if you run <code>group_by(neighborhood, sex)</code> instead of <code>group_by(sex, neighborhood)</code>, you'll get the same result, although it will be ordered differently:

```
yao %>%
  group_by(neighborhood, sex) %>%
  summarize(mean_age = mean(age))
```

`summarise()` has grouped output by 'neighborhood'. You can override using
the `.groups` argument.

```
## # A tibble: 18 × 3
## # Groups: neighborhood [9]
##
    neighborhood sex     mean_age
##
     <chr>
           <chr> <dbl>
## 1 Briqueterie Female
                           31.6
                           33.7
## 2 Briqueterie Male
                           28.2
##
   3 Carriere Female
   4 Carriere
                Male
                           30.0
##
## 5 Cité Verte Female
                           31.8
## 6 Cité Verte Male
## 7 Ekoudou Female
## 8 Ekoudou Male
                           29.3
                           25.2
                           30.2
## 9 Messa
               Female
Male
                           23.9
## 10 Messa
## 11 Mokolo
                Female
                           28.0
## 12 Mokolo
                Male
                           30.5
## 13 Nkomkana Female
## 14 Nkomkana Male
                Female
                           33.0
                           29.8
```

```
## 15 Tsinga Female 30.6
## 16 Tsinga Male 28.8
## 17 Tsinga Oliga Female 24.3
## 18 Tsinga Oliga Male 24.3
```

Now the column order is different: neighborhood is the first column, and sex is the second. And the row order is also different: rows are first ordered by neighborhood, then ordered by sex within each neighborhood.

But the actual summary statistics are the same. For example, you can again see that women from Briqueterie have a mean age of 31.6 years, while men from Briqueterie have a mean age of 33.7 years.

Using the yao data frame, group your data by gender (sex) and treatments (treatment_combinations) using group_by. Then, using summarize() and the relevant summary function, calculate the mean weight (weight_kg) for each group.

Your output should be a data frame with three columns named as shown below:

sex treatment_combinations mean_weight_kg

Using the yao data frame, group your data by age category (age_category_3), gender (sex), and IgG results (igg_result) using group_by. Then, using summarize() and the relevant summary function, calculate the mean number of bedridden days (n_bedridden_days) for each group.

Your output should be a data frame with four columns named as shown below:

age_category_3 sex igg_result mean_n_bedridden_days

Ungrouping with dplyr::ungroup() (why and how)

When you group by () more than one variable before using summarize (), the output data frame is still grouped. This persistent grouping can have unwanted downstream effects, so you will sometimes need to use dplyr::ungroup() to ungroup the data before doing further analysis.

To understand why you should ungroup () data, first consider the following example, where we group by only one variable before summarizing:

```
vao %>%
 group by(sex) %>%
 summarize(mean age = mean(age))
## # A tibble: 2 × 2
   sex mean age
 ##
 ## <chr>
           <dbl>
             29.5
## 1 Female
## 2 Male
              28.4
```

The data comes out like a normal data frame; it is not grouped. You can tell this because there is no information about groups in the header.

But now consider when you group by two variables before summarizing:

31.8

29.3 30.2

28.0

33.0

30.6

24.3 33.7

3 Female Cité Verte

8 Female Tsinga Oliga ## 9 Female Tsinga Oliga "" 10 Mola Briqueterie

4 Female Ekoudou

7 Female Nkomkana

8 Female Tsinga

5 Female Messa ## 6 Female Mokolo

##

```
yao %>%
 group by (sex, neighborhood) %>%
 summarize(mean age = mean(age))
 ## `summarise()` has grouped output by 'sex'. You can override using the
 `.groups` argument.
 ## # A tibble: 18 \times 3
 ## # Groups: sex [2]
     sex neighborhood mean age
 ##
 ##
      <chr> <chr> <dbl>
 ## 1 Female Briqueterie 31.6
 ## 2 Female Carriere
                            28.2
```

```
## 11 Male Carriere
                        30.0
## 12 Male Cité Verte
                         27.0
                        25.2
## 13 Male Ekoudou
                        23.9
## 14 Male Messa
## 15 Male Mokolo
                        30.5
## 16 Male Nkomkana
                        29.8
## 17 Male Tsinga
                        28.8
## 18 Male Tsinga Oliga
                        24.3
```

Now the header tells you that the data is still grouped by the first variable in $group_by$ (), sex:

```
# A tibble: 18 × 3

# Groups: sex [2]
```

What is the implication of this persistent grouping in the data frame? It means that the data frame may exhibit what seems like weird behavior when you try to apply some {dplyr} functions on it.

For example, if you try to select() a single variable, perhaps the mean_age variable, you should normally be able to just use select (mean_age):

```
yao %>%
  group_by(sex, neighborhood) %>%
  summarize(mean_age = mean(age)) %>%
  select(mean_age) # doesn't work as expected
```

```
## `summarise()` has grouped output by 'sex'. You can override using the
`.groups` argument.
## Adding missing grouping variables: `sex`
```

```
## # A tibble: 18 × 2
## # Groups: sex [2]
## sex mean_age
    <chr> <dbl>
##
## 1 Female
             31.6
             28.2
## 2 Female
             31.8
## 3 Female
## 4 Female
             29.3
## 5 Female
             30.2
## 6 Female
             28.0
  7 Female
             33.0
##
             30.6
## 8 Female
## 9 Female
             24.3
## 10 Male
             33.7
## 11 Male
             30.0
## 12 Male
             27.0
## 13 Male
              25.2
## 14 Male
              23.9
```

```
## 15 Male 30.5
## 16 Male 29.8
## 17 Male 28.8
## 18 Male 24.3
```

But as you can see, the grouped-by variable, sex, is *still* selected, even though we only asked for mean age in the select() statement.

This is one of the many examples of unique behaviors of grouped data frames. Other dplyr verbs like filter(), mutate() and arrange() also act in special ways on grouped data. We will address this in detail in a future lesson.

So you now know *why* you should ungroup data when you no longer need it grouped. Let's now see *how* to ungroup data. It's quite simple: just add the ungroup () function to your pipe chain. For example:

```
yao %>%
  group_by(sex, neighborhood) %>%
  summarize(mean_age = mean(age)) %>%
  ungroup()
```

```
## `summarise()` has grouped output by 'sex'. You can override using the
`.groups` argument.
```

```
## # A tibble: 18 × 3
   sex neighborhood mean age
##
##
    <chr> <chr> <dbl>
## 1 Female Briqueterie 31.6
                        28.2
## 2 Female Carriere
## 3 Female Cité Verte
                        31.8
                        29.3
## 4 Female Ekoudou
                        30.2
  5 Female Messa
                        28.0
## 6 Female Mokolo
## 7 Female Nkomkana
                        33.0
## 8 Female Tsinga
                        30.6
## 9 Female Tsinga Oliga
                        24.3
## 10 Male Briqueterie
                        33.7
                        30.0
## 11 Male Carriere
## 12 Male Cité Verte
                        27.0
## 13 Male Ekoudou
                        25.2
## 14 Male Messa
                        23.9
## 15 Male Mokolo
                        30.5
## 16 Male Nkomkana
                        29.8
## 17 Male Tsinga
                        28.8
## 18 Male Tsinga Oliga
                        24.3
```

Now that the data frame is ungrouped, it will behave like a normal data frame again. For example, you can <code>select()</code> any column(s) you want; you won't have some unwanted columns tagging along:

```
yao %>%
 group by (sex, neighborhood) %>%
 summarize(mean age = mean(age)) %>%
 ungroup() %>%
 select (mean_age)
 ## `summarise()` has grouped output by 'sex'. You can override using the
 `.groups` argument.
 ## # A tibble: 18 × 1
 ##
    mean age
       <dbl>
 ##
 ## 1 31.6
        28.2
 ## 2
 ## 3
         31.8
        31.8
29.3
 ##
 ## 5
        30.2
 ## 6
        28.0
## 7
         33.0
```

You can do a lot of data science by just *counting* and occasionally *dividing*. - Hadley Wickham, Chief Scientist at RStudio

A common data summarization task is counting how many observations (rows) there are for each group. You can achieve this with the special n() function from {dplyr}, which is specifically designed to be used within summarise().

For example, if you want to count how many individuals are in each neighborhood group, you would run:

```
yao %>%
  group_by(neighborhood) %>%
  summarize(count = n())
```

```
## # A tibble: 9 × 2
## neighborhood count
## <chr> <int>
## 1 Briqueterie 106
## 2 Carriere
                236
## 3 Cité Verte
                72
## 4 Ekoudou
                 190
                48
## 5 Messa
## 6 Mokolo
                 96
## 7 Nkomkana
                 75
## 8 Tsinga
                 81
## 9 Tsinga Oliga 67
```

As you can see, the n () function does not require any arguments. It just "knows its job" in the data frame!

Of course, you can include other summary statistics in the same <code>summarize()</code> call. For example, below we also calculate the mean age per neighborhood.

```
## # A tibble: 9 × 3
## neighborhood count mean age
## <chr> <int> <dbl>
## 1 Briqueterie 106
                      32.5
## 2 Carriere 236
                      28.9
                72
## 3 Cité Verte
               72
190
                      29.9
## 4 Ekoudou
                      27.6
## 5 Messa
                48
                      27.3
                96
                      29.1
## 6 Mokolo
## 7 Nkomkana 75 31.7
## 8 Tsinga 81 29.7
## 9 Tsinga Oliga 67
                      24.3
```

Group your yao data frame by the respondents' occupation (occupation) and use summarize() to create columns that show:

- how many individuals there are with each occupation (think of the n() function)
- the mean number of work days missed (n_days_miss_work) by those in that occupation

Your output should be a data frame with three columns named as shown below:

occupation count mean_n_days_miss_work

```
Q_occupation_summary <-
   yao %>%
   _______
```

Counting rows that meet a condition

Rather than counting all rows as above, it is sometimes more useful to count just the rows that meet specific conditions. This can be done easily by placing the required conditions within the sum() function.

For example, to count the number of people under 18 in each neighborhood, you place the condition age < 18 inside sum():

```
yao %>%
  group_by(neighborhood) %>%
  summarize(count_under_18 = sum(age < 18))</pre>
```

```
## # A tibble: 9 × 2
## neighborhood count under 18
## <chr>
                         <int>
## 1 Briqueterie
                             28
## 2 Carriere
                             58
## 3 Cité Verte
                             19
## 4 Ekoudou
                             66
## 5 Messa
                            18
## 6 Mokolo
                            32
## 7 Nkomkana
                            22
                             23
## 8 Tsinga
## 9 Tsinga Oliga
                            25
```

Similarly, to count the number of people with doctorate degrees in each neighborhood, you place the condition highest_education == "Doctorate" inside sum():

```
yao %>%
  group_by(neighborhood) %>%
  summarize(count_with_doctorates = sum(highest_education == "Doctorate"))
```

```
## 3 Cité Verte 1
## 4 Ekoudou 1
## 5 Messa 2
## 6 Mokolo 0
## 7 Nkomkana 4
## 8 Tsinga 3
## 9 Tsinga Oliga 3
```

Under the hood: counting with conditions

Why are you able to use sum() which is meant to add numbers, on a condition like highest education == "Doctorate"?

Using sum() on a condition works because the condition evaluates to the Boolean values TRUE and FALSE. And these Boolean values are treated as numbers (where TRUE equals 1 and FALSE equals 0), and numbers can, of course, be summed.

The code below demonstrates what is going on under the hood in a stepby-step way. Run through it and see if you can follow.

```
CHALLENGE
```

```
demo_of_condition_sums <- yao %>%
  select(highest_education) %>%
  mutate(with_doctorate = highest_education == "Doctorate") %>%
  mutate(numeric_with_doctorate = as.numeric(with_doctorate))

demo_of_condition_sums
```

```
## # A tibble: 971 × 3
## highest_education with_doctorate numeric with doctorate
##
     <chr> < chr> < lgl>
                                                      <dbl>
## 1 Secondary
                      FALSE
## 2 University
                                                         0
                      FALSE
## 3 University
                      FALSE
                                                         0
## 4 Secondary
                      FALSE
## 5 Primary
                                                         0
                      FALSE
## 6 Secondary
                      FALSE
                                                         ()
## 7 Secondary
                                                         0
                      FALSE
## 8 Doctorate
                      TRUE
                                                         1
## 9 Secondary
                      FALSE
## 10 Secondary
                      FALSE
## # ... with 961 more rows
```

The numeric values can then be added to produce a count of rows fulfilling the condition highest_education == "Doctorate":

```
demo_of_condition_sums %>%
    summarize(count_with_doctorate = sum(numeric_with_doctorate))

CHALLENGE

## # A tibble: 1 × 1
## count_with_doctorate
## <dbl>
## 1 17
```

For a final illustration of counting with conditions, consider the treatment_combinations variable, which lists the treatments received by people with COVID-like symptoms. People who received no treatments have an NA value:

```
yao %>%
select(treatment_combinations)
```

```
## # A tibble: 971 × 1
##
    treatment combinations
    <chr>
##
## 1 Paracetamol
## 2 <NA>
## 3 <NA>
## 4 Antibiotics
## 5 <NA>
##
   6 Paracetamol--Antibiotics
##
   7 Traditional meds.
## 8 Paracetamol
## 9 Paracetamol--Traditional meds.
## 10 <NA>
## # ... with 961 more rows
```

If you want to count the number of people who received *no treatment*, you would sum up those who meet the is.na(treatment_combinations) condition:

```
yao %>%
  group_by(neighborhood) %>%
  summarize(unknown_treatments = sum(is.na(treatment_combinations)))
```

```
## # A tibble: 9 × 2
## neighborhood unknown treatments
##
   <chr>
                               <int>
## 1 Briqueterie
                                  82
## 2 Carriere
                                 192
## 3 Cité Verte
                                  46
                                 133
## 4 Ekoudou
## 5 Messa
                                  35
## 6 Mokolo
                                  65
```

```
## 7 Nkomkana 53
## 8 Tsinga 56
## 9 Tsinga Oliga 47
```

These are the people with NA values for the treatment combinations column.

To count the people who *did* receive some treatment, you can simply negate the is.na() function with !:

```
yao %>%
  group_by(neighborhood) %>%
  summarize(known_treatments = sum(!is.na(treatment_combinations)))
```

```
## # A tibble: 9 × 2
## neighborhood known_treatments
##
   <chr>
                            <int>
## 1 Briqueterie
                               24
## 2 Carriere
                               44
## 3 Cité Verte
                               26
## 4 Ekoudou
                               57
## 5 Messa
                               13
## 6 Mokolo
                               31
## 7 Nkomkana
                               22
## 8 Tsinga
                               25
## 9 Tsinga Oliga
                               20
```

Group your yao data frame by the respondents' symptoms (symptoms) and use the sum() function to count how many adults have each symptom combination.

Your output should be a data frame with two columns named as shown below:

symptoms sum_adults

dplyr::count()

The dplyr::count() function wraps a bunch of things into one beautiful friendly line of code to help you find counts of observations by group.

Let's use dplyr::count() on our occupation variable:

```
yao %>%
count(occupation)
```

```
## # A tibble: 28 × 2
## occupation
    <chr>
                                        <int>
##
## 1 Farmer
                                            5
##
   2 Farmer--Other
                                            1
                                           65
## 3 Home-maker
## 4 Home-maker--Farmer
                                           2
## 5 Home-maker--Informal worker
                                           1
## 6 Home-maker--Informal worker--Farmer
   7 Home-maker--Trader
## 8 Informal worker
                                         189
## 9 Informal worker--Other
## 10 Informal worker--Trader
                                           4
## # ... with 18 more rows
```

Note that this is the same output as:

```
yao %>%
  group_by(occupation) %>%
  summarize(n = n())
```

```
## # A tibble: 28 × 2
## occupation
                                            n
     <chr>
##
                                        <int>
## 1 Farmer
## 2 Farmer--Other
                                            1
## 3 Home-maker
                                            65
## 4 Home-maker--Farmer
                                            2
## 5 Home-maker--Informal worker

                                                      6
## # ... with 30 more rows
```

The <code>count()</code> verb gives you key information about your dataset in a very quick manner. Let's look at our IgG results stratified by age category and sex in one line of code.

Using the yao data frame, count the different combinations of gender (sex), age categories (age category 3) and IgG results (igg result).

Your output should be a data frame with four columns named as shown below:

sex age_category_3 igg_result n

```
Q_count_iggresults_stratified_by_sex_agecategories <-
yao %>%
______
```

Using the yao data frame, count the different combinations of age categories (age_category_3) and number of bedridden days (n bedridden days).

Your output should be a data frame with three columns named as shown below:

```
age_category_3 n_bedridden_days n
```

The downside of count() is that it can only give you a single summary statistic in the data frame. When you use summarize() and n() you can include multiple summary statistics. For example:

`summarise()` has grouped output by 'sex'. You can override using the
`.groups` argument.

```
## # A tibble: 18 × 4
## # Groups: sex [2]
##

                       39
## 17 Male Tsinga
## 18 Male Tsinga Oliga 37
```

6 Male Senior

Including missing combinations in summaries

When you use <code>group_by()</code> and <code>summarize()</code> on multiple variables, you obtain a summary statistic for every unique combination of the grouped variables. For instance, consider the code and output below, which counts the number of individuals in each age-sex group:

```
yao %>%
 group by (sex, age category 3) %>%
  summarise(number of individuals = n())
 ## `summarise()` has grouped output by 'sex'. You can override using the
 `.groups` argument.
 ## # A tibble: 6 × 3
 ## # Groups: sex [2]
    sex age category 3 number of individuals
 ## <chr> <chr>
                                           <int>
 ## 1 Female Adult
                                             368
 ## 2 Female Child
                                             155
 ## 3 Female Senior
                                              26
 ## 4 Male Adult
                                             267
 ## 5 Male Child
                                             136
```

In the output data frame, there is one row for each combination of sex and age group (Female–Adult, Female–Child and so on).

19

But what happens if one of these combinations is not present in the data?

Let's create an artificial example to observe this. With the code below, we artificially drop all male children from the yao data frame:

```
yao_no_male_children <-
yao %>%
filter(!(sex == "Male" & age_category_3 == "Child"))
```

Now if you run the same group_by() and summarize() call on yao_no_male_children, you'll notice the missing combination:

```
yao no male children %>%
 group by (sex, age category 3) %>%
 summarise(number of individuals = n())
 ## `summarise()` has grouped output by 'sex'. You can override using the
 .groups argument.
 ## # A tibble: 5 × 3
 ## # Groups: sex [2]
 ## sex age category 3 number of individuals
     <chr> <chr>
 ##
 ## 1 Female Adult
                                             368
                                             155
 ## 2 Female Child
 ## 3 Female Senior
                                             26
 ## 4 Male Adult
                                             267
 ## 5 Male Senior
                                             19
```

Indeed, there is no row for male children.

But sometimes it is useful to include such missing combinations in the output data frame, with an NA or 0 value for the summary statistic.

To do this, you can run the following code instead:

```
\#\# `summarise()` has grouped output by 'sex'. You can override using the `.groups` argument.
```

```
## # A tibble: 6 × 3
## # Groups: sex [2]
## sex age_category_3 number_of_individuals
## <fct> <fct> <int>
## 1 Female Adult 368
## 2 Female Child 155
## 3 Female Senior 26
## 4 Male Adult 267
```

```
## 5 Male Child 0
## 6 Male Senior 19
```

What does the code do?

- First it converts the grouping variables to factors with as.factor() (inside a mutate() call)
- Then it uses the argument .drop = FALSE in the group_by() function to avoid dropping the missing combinations.

Now you have a clear 0 count for the number of male children!

Let's see one more example, this time without artificially modifying our data.

The code below calculates the average age by sex and education group:

```
yao %>%
  group_by(sex, highest_education) %>%
  summarise(mean_age = mean(age))
```

```
## `summarise()` has grouped output by 'sex'. You can override using the
`.groups` argument.
```

```
## # A tibble: 13 × 3
## # Groups: sex [2]
## sex highest_education mean_age
                             <dbl>
##
    <chr> <chr>
## 1 Female Doctorate
                                28
## 2 Female No formal instruction 45.6
  3 Female No response
                                 35
## 4 Female Primary
                                 26.8
## 5 Female Secondary
                                28.8
## 6 Female University
                                 31.5
## 7 Male Doctorate
                                 42.2
## 8 Male No formal instruction
                                 37.9
## 9 Male No response
                                 22
                                 5.5
## 10 Male Other
## 11 Male Primary
                                22.9
## 12 Male Secondary
                                29.4
## 13 Male University
                                 31.9
```

Notice that in the output data frame, there are 7 rows for men but only 6 rows for women, because no woman answered "Other" to the question on highest education level.

If you nonetheless want to include the "Female–Other" row in the output data frame, you would run:

`summarise()` has grouped output by 'sex'. You can override using the
`.groups` argument.

```
## # A tibble: 14 × 3
## # Groups: sex [2]
## sex highest education mean age
                <dbl> ate 28
##
    <fct> <fct>
## 1 Female Doctorate
## 2 Female No formal instruction
                                45.6
  3 Female No response
                                35
                              NaN
## 4 Female Other
## 5 Female Primary
                               26.8
## 6 Female Secondary
                                28.8
## 7 Female University
                                31.5
## 8 Male Doctorate
                                42.2
## 9 Male No formal instruction 37.9
## 10 Male No response
                                22
## 11 Male Other
                                 5.5
## 12 Male Primary
                                22.9
## 13 Male Secondary
                                29.4
## 14 Male University
                                31.9
```

Using the yao data frame, let's calculate the median age when grouping by neighborhood, age_category, and gender

Note, we want all possible combinations of these three variables (not just those present in our data).

Pay attention to two data wrangling imperatives!

- convert your grouping variables to factors beforehand using mutate()
- calculate your statistic, the median, while removing any NA values.

Your output should be a data frame with four columns named as shown below:

neighborhood age_category_3 sex median_age

```
Q median age by neighborhood agecategory sex <-
  yao %>%
```

Why include missing combinations?

Above, we mentioned that including missing combinations is often useful in the data analysis workflow. Let's see one use case: plotting with {ggplot}. If you have not yet learned {ggplot}, that is okay, just focus on the plot outputs.

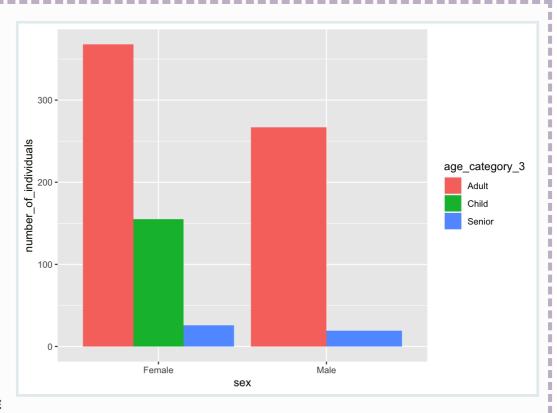

To make a dodged bar chart with the age-sex counts of yao no male children, you could run:

SIDE NOTE

```
yao_no_male_children %>%
  group by (sex, age category 3) %>%
  summarise(number of individuals = n()) %>%
  ungroup() %>%
  # pass the output to ggplot
  ggplot() +
  geom_col(aes(x = sex, y = number_of_individuals, fill =
        age_category_3),
           position = "dodge")
```

`summarise()` has grouped output by 'sex'. You can override using the `.groups` argument.

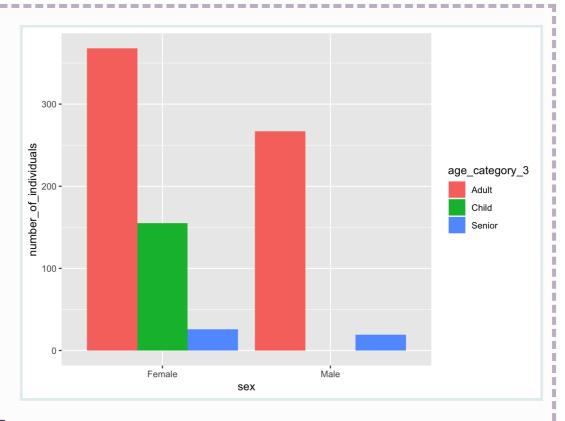

SIDE NOTE

Not very elegant! Ideally there should be an empty space indicating 0 for the number of male children.

If you instead implement the procedure to include missing combinations, you get a more natural dodged bar plot, with an empty space for male children:

`summarise()` has grouped output by 'sex'. You can override
using the `.groups` argument.

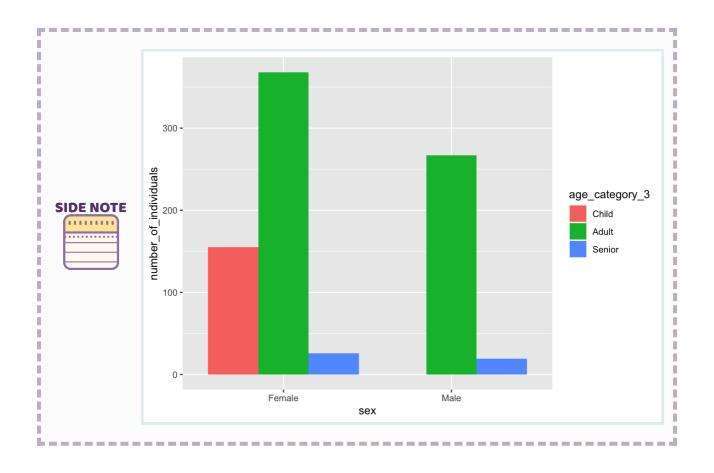

SIDE NOTE

Much better!

By the way, this output can be improved slightly by setting the factor levels for age to their proper ascending order: first "Child", then "Adult" then "Senior":

`summarise()` has grouped output by 'sex'. You can override
using the `.groups` argument.

Wrap-up

You have now seen how to obtain quick summary statistics from your data, either for exploratory data or for further data presentation or plotting.

Additionally, you have discovered one of the marvels of {dplyr}, the possibility to group your data using $group\ by()$.

 ${\tt group_by}$ () combined with ${\tt summarize}$ () is a one of the most common grouping manipulations.

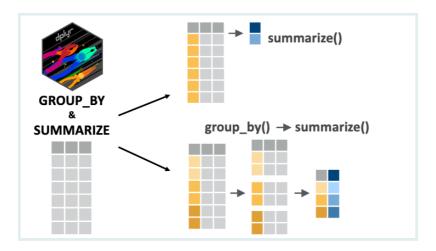

Fig: summarize() and group_by()

However, you can also combine $group_by()$ with many of the other {dplyr} verbs: this is what we will cover in our next lesson. See you soon!
